Grassland covers about 10 million acres in Florida and most of this area is grazed by beef cattle. Rapid urbanization is reducing grassland area and may require that beef producers use pastures more efficiently in the future. Grazing method is one management tool that can be used to increase the efficiency of forage and animal production.

methods include rotational or continuous grazing. Rotational grazing is defined as alternating periods of grazing and rest for two or more paddocks in a grazing management unit throughout the grazing season. Continuous grazing is a method of grazing livestock on a specific unit of land where animals have unrestricted and uninterrupted access throughout the grazing season. Rotational grazing has shown advantages over continuous grazing in several measures of forage and beef cattle production. In the following sections, we will describe some of the benefits of rotational grazing for forage production and utilization, animal production, nutrient distribution, and management flexibility. Potential disadvantages will also be mentioned.

Before discussing the advantages and disadvantages of rotational grazing, it is important to note that the most critical grazing management decision is not grazing method but stocking rate. Stocking rate is defined as the amount of land allotted to each animal during the grazing season. If the stocking rate is incorrect, then neither rotational nor continuous grazing will correct the problem. So, the first and most important step in developing a grazing program is to choose the correct stocking rate for your conditions. After that is done, changing grazing method may allow you to fine tune your grazing system.

Production of new growth after grazing depends upon the amount of residual leaf and carbohydrate reserves because they will supply energy for plant growth. Rotational grazing with the correct stocking rate will maintain adequate stubble height and carbohydrate reserves after grazing to maximize forage regrowth. Stewart et al. (2005) verified that bahiagrass (*Paspalum notatum*) under rotational grazing can produce more forage than under continuous grazing (Table 1). Rotational grazing with 1, 3, 7, and 21 days of pasture occupation (21-day rest period between grazing events) resulted in greater forage production than pastures that were grazed continuously.

Table 1. Forage production on rotationally grazed pastures with different grazing periods (rest period of 21 days for all) and under continuous grazing during 2001-2003. Adapted from Stewart et. al. (2005)

Treatment	Forage Production (lb of DM per acre per day)
Rotational	
1 day	58
3 days	61
7 days	64
21 days	67
Continuous	37

In addition to increased regrowth rates, rotational grazing at the proper stocking rate also aids in pasture persistence by allowing better stubble height control. Controlling target stubble height on rotationally grazed pastures is important, not only to maximize forage regrowth, but also to extend the life span of the pastures. Overgrazing can result in loss of desirable species and an increase in weeds. Target stubble heights for persistence of different warm-season grasses are shown in Table 2.

Table 2. Target stubble height for persistence of rotationally grazed warm-season grasses in Florida.

Species	Target stubble height (inches)
Bahiagrass	2
Bermudagrass	3-4
Stargrass	6-8
Limpograss	8-10

Results from Florida studies confirm the beneficial effect of rotational grazing on persistence of some grasses. For example, Callie bermudagrass pastures were rotationally or continuously grazed for two years at the same stocking rate. Pastures contained 90% Callie and 10% common bermudagrass at the beginning of the study. After two years of grazing, Callie percentage was 86% in rotationally grazed pastures and 62% in continuously grazed pastures. Callie persisted better under rotational grazing because it grew taller and shaded common bermudagrass during the rest period between grazing events, while under continuous grazing the lower-growing common bermudagrass was not shaded nearly as much.

Rotational grazing has the potential to increase grazing efficiency, which is the proportion of forage produced that animals consume. In continuously grazed pastures, a greater proportion of forage is trampled, soiled, and rejected by the animals than in rotationally grazed pastures.

Forage nutritive value is usually not affected by grazing method. In Florida, bahiagrass crude protein, phosphorus, and digestibility were not affected by grazing method or length of the grazing period of rotationally grazed pastures.

In general, grazing method does not affect average daily gain of beef cattle grazing warm-season grasses; however, the greater forage production and utilization allow greater stocking rates that typically result in greater liveweight gain per unit of land. Stocking rates could be increased by as much as 20% when bermudagrass pastures were rotationally versus continuously grazed. Average daily gain did not differ between grazing methods and averaged 1.10 lbs/day. However, the increase in stocking rate with similar average daily gains resulted in greater liveweight gains per acre.

Grazing cattle retain approximately 20% of the nutrients ingested from forages and the remaining 80% is excreted through feces and urine. Feces and urine are important sources of nutrients for forages, mainly for grazing systems with low inputs. However, in warm climates, the animals tend to concentrate their excreta close to water and shade. Under continuous grazing in warm climates, animals deposited 80% of the excreta in 30-40% of the pasture area. Rotational grazing increases the uniformity of distribution of the excreta. (Figure 1).

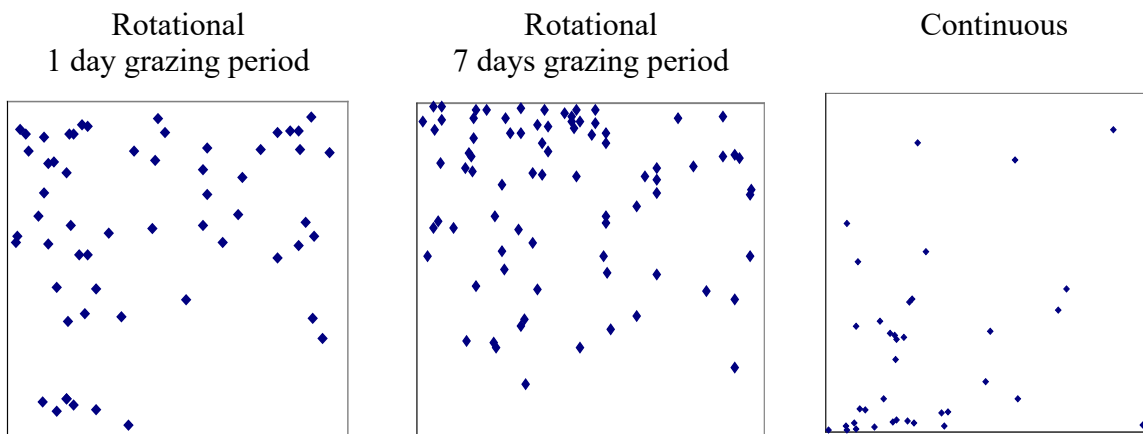

Figure 1. Feces distribution of beef heifers grazing bahiagrass pastures using different grazing methods at equal stocking rates. Dots represent feces events during 24-hour periods. Resting period for rotational grazing was 21 days. Adapted from Dubeux et al. (2006).

At times of increasing fertilizer costs, better distribution of the excreta likely results in improved use of the nutrients by forages and may reduce the amount of commercial fertilizers used in the long run.

Rotational grazing allows producers to make management decisions based on the seasonal variability in forage production and animal requirements. During the months of the year with excessive forage production, rotational grazing allows some pastures to be deferred and used for hay production or stockpiled forage for the winter. In addition, the producer utilizing rotational grazing has the opportunity to better match animal requirements with the pasture's ability to supply nutrients. Animals with greater nutrient requirements (i.e., replacement heifers, first calf heifers) can have access to pastures first and graze the greater nutritive value forage. They can be followed by cattle with lower nutrient requirements (i.e., mature cows). Lastly, the

periodic handling of the cattle permits managers to inspect the herd frequently so that timely herd management decisions can be made.

The main disadvantages of rotational grazing compared with continuous grazing include:

- initial investment on fences, water, and feed bunks
- labor availability to move the animals
- more management decisions

In conclusion, no single grazing management program will be appropriate for all forages in all environments. Because of the likelihood of greater forage production and pasture persistence, rotational grazing has potential to increase animal production on beef cattle operations in Florida. The choice of grazing method will depend on the characteristics of a particular beef cattle

enterprise including the forage being grazed, the stocking rate used, and the economics of production. In general, rotational grazing will be most needed when stocking rates are high or the forage being grazed requires more careful management for long-term survival (e.g., stargrass and limpgrass).

Upcoming Events

Ona Graduate Student Highlight with Jaime Garzon – March 8, 11:00 – 11:45 a.m. He will be presenting, “Ecosystem Service of Overseeding Aeschynomene into Bahiagrass Pastures.” Jaime is an agronomy PhD student under the advisement of Dr. Joao Vendramini.

Forage Management Tour & Workshop – March 10, 9:00 a.m. – 1:00 p.m., Mudge Ranch, 1323 Loblolly Bay Road, LaBelle. For more information, contact: forages@ifas.ufl.edu

UF/IFAS Range Cattle REC - 3401 Experiment Station Rd., Ona - <http://rcrec-ona.ifas.ufl.edu/>
